Abstract
Retrotransposons are considered a possible source for mutations due to their potential of spreading in the genome using a “copy and paste”-like mechanism. Here we report on the isolation and characterization of a new Ty3-gypsy retrotransposon from allotetraploid peanut (Arachis hypogaea, 2n=4x=40) and its diploid ancestors A. duranensis (AA-genome, 2n=20) and A. ipaënsis (BB-genome, 2n=20). We have identified two repetitive sequences, one showing high similarity at the amino acid level to the reverse transcriptase of Athila-type retrotransposons, the other being AT-rich with no similarities to gene bank sequences. Results from genome walking experiments gave first evidence that both sequences represented parts of the same Ty3-gypsy retrotransposon, the 5‘-LTR (long terminal repeat)- and the pol (polyprotein)-region respectively. Fluorescent in situ hybridization (FISH) experiments showed that the element is dispersedly distributed on the chromosomes, absent from centromeres and telomeric regions, and more prominent in chromosomes of the A-genome. The element appeared to be moderately repetitive with copy numbers of about 830 (A. ipaënsis), 2,600 (A. duranensis), and 3,000 (Arachis hypogaea) per haploid genome. Phylogenetic analysis of the deduced amino acid sequences of 80 isolated reverse transcriptase clones from the three species shed light on its evolution within the peanut species. The isolated sequences contained multiple stop-codons and so far, no evidence has been found that the element is still active. An outlook is given regarding finding new tools for the advancement of Arachis breeding programs aimed at the transfer of resistance to biotic and abiotic stresses to peanut.

Introduction
Cultivated peanut (Arachis hypogaea) is an allotetraploid species (AABB genome, 2n = 4x = 40), which derived from a single hybridization event between two diploid genome, 2n = 4x = 40), which derived from a single hybridization event of A. ipaënsis (BB-genome, 2n=20) and A. duranensis (AA-genome, 2n=20) of cultivated peanut (Arachis hypogaea), 2n=4x=40) and its diploid ancestors A. duranensis (AA-genome, 2n=20) and A. ipaënsis (BB-genome, 2n=20). We have identified two repetitive sequences, one showing high similarity at the amino acid level to the reverse transcriptase of Athila-type retrotransposons, the other being AT-rich with no similarities to gene bank sequences. Results from genome walking experiments gave first evidence that both sequences represented parts of the same Ty3-gypsy retrotransposon, the 5‘-LTR (long terminal repeat)- and the pol (polyprotein)-region respectively. Fluorescent in situ hybridization (FISH) experiments showed that the element is dispersedly distributed on the chromosomes, absent from centromeres and telomeric regions, and more prominent in chromosomes of the A-genome. The element appeared to be moderately repetitive with copy numbers of about 830 (A. ipaënsis), 2,600 (A. duranensis), and 3,000 (Arachis hypogaea) per haploid genome. Phylogenetic analysis of the deduced amino acid sequences of 80 isolated reverse transcriptase clones from the three species shed light on its evolution within the peanut species. The isolated sequences contained multiple stop-codons and so far, no evidence has been found that the element is still active. An outlook is given regarding finding new tools for the advancement of Arachis breeding programs aimed at the transfer of resistance to biotic and abiotic stresses to peanut.

Retrotransposons are mobile genetic elements present in many different organisms. Active elements replicate through a mechanism of reverse transcription and insertion of a new copy into new chromosomal sites, where they can cause mutations (for a recent review on their life cycle see [3]). Retroelements, particularly the LTR (long terminal repeat) retrotransposons, constitute the major part of repetitive DNA and contribute substantially to genome size [4, 5]. Based on phylogenetic analysis of their reverse transcriptase (rt) sequences and on structural differences LTR-, retrotransposons can be divided into two major lineages, one consisting of the Ty1-copia retrotransposons (pseudoviridae), and the other of the Ty3-gypsy retrotransposons (metavirus) [6, 7]. Retrovirus-like retrotransposons are characterized through an additional open reading frame (ORF) encoding transmembrane domains, which are characteristic for envelope (env) genes. Examples of retrovirus-like transposon families are the Ty3-gypsy retrotransposons Athila [8], Cyclops [9], and Calypso [10]. Several LTR-retrotransposons have been reported to be present in legumes. The first indication for presence of an LTR retrotransposon in peanut was given by Chavanne, et al. [9], who characterized the gypsy-like retrotransposon Cyclops in pea and detected hybridization of a fragment of its reverse transcriptase to genomic DNA of various legumes, including A. hypogaea. Yüksel, et al. [11] screened their BAC library of A. hypogaea and found a sequence with similarity to an Arabidopsis copia element.

Some elements seem to be constitutively expressed, for instance the Ogre element of pea [12]. Others are silent and can be activated upon certain stress signals such as tissue culture (Tos17 retrotransposon in rice [13]), ionizing irradiation (Ty1 in Saccharomyces cerevisiae [14]), wounding (Tso1 in tobacco [15]), or allopolyloidization (Wis2-1A in synthetic wheat allotetraploids [16]). The ability of some retrotransposons to become active again after stimulation makes them an ideal tool for inducing desired genetic variability, and also for reverse genetics approaches, as it was shown by the generation of about 50,000 rice insertion lines with Tos 17 [17]. Furthermore, their abundance and ability to transpose make them good potential markers in form of the PCR-based techniques IRAP (inter-retrotransposon amplified polymorphism) and REMAP (retrotransposon-microsatellite amplified polymorphism) that detect retrotransposon integration events in the genome [18].

So far, with the exception of rDNA sequences [1] relatively little is known about the features and localization of repetitive elements in Arachis species. This applies especially to retrotransposons. Here we report on the isolation and characterization of a new Athila-like retrotransposon in Arachis species.

Materials and Methods
Plant materials and DNA extraction: Leaf and root tissue were obtained from A. hypogaea cv. Tatu, A. duranensis (accession V14167c), A. stenosperma (accession V10309), and A. ipaënsis (accession KG30076c). Plants were grown from seeds under greenhouse conditions. All plants were obtained from the Brazilian Arachis germplasm collection, maintained at Embrapa Genetic Resources and Biotechnology — CENARGEN (Brasilia-DF, Brazil).

Cloning of reverse transcription sequences and phylogenetic analysis: To enable phylogenetic analysis of the retroelement in A. hypogaea, A.

**Results**

**Isolation and structure of the *Arachis* retroelement:** Based on a dot blot survey of short insert libraries of *A. duranensis* and *A. ipaënsis* that were probed with genomic DNA of both species, several clones were identified resembling repetitive sequences. Using the sequences of these clones and additional gene bank sequences, two pseudo-contigs, Rep-1 and Rep-2, were established using the Staden-Package software [19]. A BLASTx search [25] revealed high similarities between one of those contigs (Rep-2) and the reverse transcriptase region of the Ty3-gypsy retrotransposon *Athila*. On the other hand, the Rep-1 contig was AT-rich with no similarities to any genomic sequences in gene bank. Extended sequence information from both repeats was gained through a modified genome walker strategy, involving the ligation of specific adaptors to genomic restriction fragments and subsequent amplification of sequences adjacent to the repeat clones using adaptor- and repeat-specific primers. From 24 clones isolated from the right site of Rep-1, three had inserts of 1200 to 2000 bps (Fig. 1). Those three inserts showed significant similarity (2e-32) to the gag-pol region of the Ty3-gypsy retrotransposons *Ogre* (pea) and *Athila* (*Arabidopsis*). Additionally, the new sequences resembled at their 5’-end the primer-binding site (PBS) of *Calypso*- and *Athila* like retrotransposons, which is complementary to the 3’-end of the Asp tRNA. Translated sequences received from Rep-2 genome walking experiments revealed presence of conserved amino acid motifs that are characteristic for the retrovirus-like Ty3-gypsy elements. These results gave first evidence that Rep-1 and Rep-2 are parts of the LTR- and the pol region of the same Ty3-gypsy retrotransposon. We aimed to obtain the full sequence of this element using the recently generated BAC libraries of the *A. duranensis* and *A. ipaënsis* genomes [26]. Using PCR screening and Southern hybridization, four BAC clones have been identified that contain at least one rt- and two or more LTR-fragments, which implies the possibility of isolation of a complete element. According to preliminary results from PCR cloning the total length of the element is bigger than 11,000 bps and does not contain an env-typical ORF.

**Copy Number Estimation:** Copy number estimations have been made on the basis of non-radioactive dot blot hybridizations of a retrotransposon subclone against dilution series of itself and of genomic DNA from the three *Arachis* species. Subclone dilutions represented one to 100,000 copies of the retrotransposon sequence in 500 ng of genomic DNA. The strength of hybridization signals in the chemilumigraphs was quantified using the MultiGauge software (Fucifilm) and the slope of the regression curves of the resulting plots have been used for calculating the copy numbers. The representative rt-subclone Ah-9 was estimated to be present in the *A. ipaënsis* genome (2C = 2.8 pg) with about 830 copies (equivalent to 0.7% of the genome), in *A. duranensis* (2C = 2.61 pg) with about 2,600 copies (equivalent to 2.3% of the genome), and in *A. hypogaea* (2C = 5.93 pg) with 3,000 copies (equivalent to 1.2% of the genome) per haploid genome. (Genome sizes according to Temsch and Greilhuber [27, 28].)

**Chromosomal Distribution of retroelement:** To determine the chromosomal distribution of the retrotransposon metaphase spreads of *A. duranensis*, *A. stenosperma* (A-genome), and *A. hypogaea* were hybridized with Dig-labeled LTR- and reverse transcriptase probes.
DAPI staining of the chromosomes revealed centromeric bands, which are typical for the Arachis A-genome, whereas B-genome chromosomes do not show such bands [1]. Hybridization of A-genome chromosome spreads with the LTR probe showed dispersed distribution of the element in euchromatic regions of chromosomes and absence from heterochromatic regions, such as the centromere and telomeric regions (Fig. 2). When hybridized to metaphase spreads of A. hypogaea, the same probe appeared to be localized preferably in the A-genome of Arachis, which became obvious by comparison with the DAPI stained spreads allowing differentiation between A- and B-genome chromosomes. This kind of preferential hybridization to the A-genome was also detected when using a clone representing the reverse transcriptase as a probe (data not shown).

**Phylogenetic Analysis:** From 87 reverse transcriptase sequences isolated and cloned from A. hypogaea, A. duranensis, and A. ipaënsis, 80 have been selected for analysis of their evolution. Using Mega 3.1 the genetic distances between the sequences were calculated (Table 1). Three groups are shown, each of them contains all sequences of one species. The distances within each group and between the groups have been analyzed with regard to the nucleotide and as well the amino acid sequences. The data reveal that the DNA sequences isolated from A. duranensis suffered less modifications as compared to the ones from A. hypogaea and A. ipaënsis, which revealed the largest genetic distances. This trend is even more obvious when looking at the amino acid sequences, probably a result of changes in the reading frame that could have generated different amino acids.

**Table 1.** Genetic distances between DNA sequences and between amino acid sequences of isolated rt-genes from A. hypogaea (Ah), A. duranensis (Ad), and A. ipaënsis (Ai). The mean value corresponds to all 80 sequences of DNA and/or amino acids.

**Discussion**

The present work evolved from our efforts in isolating repetitive elements from the A- and B-genome of Arachis aimed at finding out more about the genomic relationships between the ancestors of cultivated peanut. The described element is the first characterized retrotransposon in Arachis. Preliminary sequencing results revealed that it belongs to the Ty3-gypsy retrotransposon family with high similarities to retrovirus-like elements, particularly to the Athila element from Arabidopsis. However, it also became clear that this new element has its own characteristics, which make it different from the related elements. FISH analysis has shown its localization in the euchromatic region of the chromosomes, and absence from centromeric and telomeric regions. This kind of distribution pattern was shown to be typical for Ty1-copia elements, such as BARE [30]. In contrast, the Athila element in Arabidopsis is associated with centromeric and pericentromeric regions [31]. We have detected preferential hybridization of the Arachis element to A-genome chromosomes. These results were substantiated by copy number estimations, where more than three times less copies were estimated for A. ipaënsis than for A. duranensis. Since multiple insertions of the element were found in A. hypogaea, A. ipaënsis, A. duranensis, and A. stenosperma, it can be assumed that it is an ancient component of the genus. In a phylogenetic analysis of 80 rt-sequences isolated from all three species, fewer mutations were found between the sequences derived from A. duranensis as compared to the ones from A. ipaënsis. We conclude that the element was present in the common ancestor of the Arachis wild species at low copy number. After differentiation it amplified in A. duranensis, whereas in A. ipaënsis the amplification was low, the copy number remained stable or was even reduced through elimination. We could not find evidence for activity of the element by screening all relevant EST databases. It appeared that all sequences isolated included stop codons. Using BAC sequences we are now on the way to a more detailed analysis of this element. Further efforts are directed towards identifying elements, which can be activated thus enabling their use for induced mutations approaches.
